We would like to thank Rachana Bhatt, Daniel Fetter and Christine Schwartz for their helpful comments. We would also like to thank seminar participants at the University of California San Diego, University of Essex, University of Kentucky, London School of Economics, Texas A & M University, University of Texas-Austin, and participants in the All UC Labor Economics Workshop, American Education Finance and Policy Annual Meeting, the Bergen-Stavanger Workshop, University of Michigan Conference on the Long-Run Impacts of Early Life Events, and Society of Labor Economics annual meeting.

Abstract

World War II and its subsequent G.I. Bill have been widely credited with playing a transformative role in American society, but there have been few quantitative analyses of these historical events' broad social effects. We exploit between-cohort variation in the probability of military service to investigate how WWII and the G.I. Bill altered the structure of marriage, and find that it had important spillover effects beyond its direct effect on men's educational attainment. Our results suggest that the additional education received by returning veterans caused them to "sort" into wives with significantly higher levels of education. This suggests an important mechanism by which socio-economic status may be passed on to the next generation.

Keywords: Marital Sorting, Education, WWII G.I. Bill

World War II and its subsequent G.I. Bill have been widely credited with playing a transformative role in American society. The end of the war created a surge of veterans on college campuses—veterans accounted for over 70% of male enrollment in the immediate post-war years—and research has shown that these increases were related to the availability of postwar educational benefits combined with military service. Bound and Turner (2002), for example, document that World War II and the G.I. Bill increased collegiate completion rates by approximately 40%. The "legend" of the WWII G.I. Bill extends beyond its direct effects on education, however. For example, in his book *When Dreams Come True: The G.I. Bill and the Making of Modern America* (1996), Michael Bennett concludes that "Quite literally, the G.I. Bill changed the way we live, the way we house ourselves, the way we are educated, how we work and at what, and how we eat and transport ourselves." Similarly, Drucker (1993) states that "Future historians may consider it the most important event of the 20th century…already it has changed the political, economic and moral landscape of the world."

In spite of this rhetoric, there have been few quantitative analyses of the G.I. Bill's broader social effects. This is somewhat surprising because the bill's combined breadth and generosity surpass that of any other education policy in modern America. Furthermore, a burgeoning literature documents that in the modern context, exogenous shocks to education causally reduce crime, improve health, and increase human capital among individuals' offspring.¹ Thus, it is plausible that the increase in education associated with WWII and the G.I. Bill had important spillover effects.

¹ e.g. Currie and Moretti, 2003; Lleras-Muney, 2005; Oreopolous, Page and Stevens, 2006; Lochner and Moretti, 2004; Maurin and McNally, 2008; Page, 2007.

The aim of this paper is to document how WWII and the G.I. Bill affected the marital outcomes of returning veterans. In doing so, we hope to shed light on how these historical events affected a dimension of American society that is both interesting in its own right, and has important implications for the intergenerational transmission of socioeconomic status.² Our analyses also provide insights into the mechanisms underlying assortative mating, which are not well understood. We use cross-cohort variation in military service rates to identify these effects, essentially exploiting the fact that sharp differences in the timing of an individual's date of birth lead to different opportunities for men whom we would otherwise expect to be very similar.

We find evidence that World War II and the G.I. Bill had substantive effects on marital sorting. Cohorts who were eligible for G.I. benefits married women who had approximately 0.4 more years of education than cohorts who just missed the eligibility cutoff. Their wives were also discontinuously older. The most likely mechanism is that men's marital opportunities were changed by the additional education that the G.I. Bill provided. WWI veterans did not receive educational benefits, and when we use a similar estimation strategy to examine WWI cohorts we do not find evidence of discontinuous changes in either their own or their wives' education levels. This suggests that our results are not driven by the effects of military service itself. Nor do they appear to be driven by G.I. housing benefits, combat related differences in the sex ratio, changes in women's educational opportunities, or changes in women's human capital investments after marriage. Our findings add to the mounting evidence that individuals' education investments have important spillover effects, and that the well documented

 $^{^{2}}$ See, for example, Mare and Maralani's (2006) model of intergenerational mobility, in which the positive relationship between parental education and the education of one's offspring is enhanced by the impact of education on marital sorting and mitigated by the impact of education on fertility.

associations between education and other measures of well-being are not simply an artifact of cross-sectional variation in innate characteristics.

The remainder of the paper is organized as follows: Section I provides a brief overview of World War II and the G.I. Bill, and motivates our interest in looking at how these historical events affected assortative mating. Sections II and III outline our estimation strategy and data, respectively. Section IV presents the results. In Section V we offer greater clarification about the mechanisms, and Section VI provides concluding thoughts.

I. Background

The G.I. Bill is widely regarded as one of the most significant education policies to have taken place in modern America. Signed into law on June 22, 1944, it provided unprecedented educational aid to returning veterans who had served for at least 90 days or had been discharged early because of disabilities acquired during service. Anyone who had served on active duty between September 1940 and July 1947 was eligible for support, provided that he began his schooling before July 1951. The number of years of benefits for which a veteran qualified was determined by the individual's age and length of service, and ranged from one to four years. Most veterans were eligible for all four years of benefits.

The G.I. Bill offered very generous financial provisions. It provided full tuition, books and supplies towards virtually any institution of higher education in the country, as well as a monthly stipend that varied by family size. Previous studies have estimated that for a single veteran this cash allowance was equal to about half the opportunity cost of not working, and for a married veteran it was equal to about 70% of the opportunity cost.³

³ Bound and Turner (2002)

The effect of this legislation on men's schooling has been thoroughly investigated by Bound and Turner (2002) and by Stanley (2003).⁴ Bound and Turner estimate that G.I. benefits increased white men's collegiate attainment by about 40%, using between-cohort differences in military service generated by wartime changes in manpower requirements to identify the likelihood that an individual was benefit eligible. Stanley's estimates are based on comparisons of postsecondary education levels among cohorts of veterans who were less likely to avail themselves of the G.I. Bill because they had already completed their education to those who likely entered the military straight out of high school. This estimation strategy suggests that among veterans born between 1923 and 1926 the G.I. Bill increased postsecondary education levels by about 20%.

These empirical strategies are motivated by concerns about selection into military service. Comparisons of educational attainment between veterans and non-veterans are likely to lead to overestimates of the legislation's effect because one of the primary reasons for deferment from WWII service was physical or mental disability.⁵ Since individuals with low mental capacity probably had lower levels of education than average, veteran status alone is unlikely to identify the effects of the G.I. Bill.

Bound and Turner's identification strategy gets around this problem by comparing outcomes for birth cohorts whose eligibility fell on either side of the sharp decline in manpower needs after 1945. Figure 1 documents the dramatic variation in WWII participation across

⁴ In a related study, Lemieux and Card (2001) estimate the effect of the Canadian G.I. Bill on education and earnings.

⁵Among 19-25 year old men deferred in 1945, for example, 56% were deemed physically or mentally unfit (Bound and Turner, 2002).

cohorts and provides some intuition behind their estimation strategy.⁶ About 30% of men born in 1910 were enlisted, and enlistment rates show a rapid increase among those born between 1914 and 1919. Military service was voluntary until 1940, when Congress passed the Selective Service Act, which mandated registration of young men and required enlistment among those who were deemed eligible. As a result, cohorts born between 1920 and 1926, who would have been subject to the draft, experienced participation rates that were nearly constant, at roughly 80%. Among those who turned 18 after V-J day (cohorts born after the third quarter of 1927), service plummeted. Since the draft produces a sharp correlation between benefit eligibility and an individual's birth date, but birth cohort is unlikely to be correlated with other innate characteristics, a comparison of education levels between pre-1927 and post-1927 cohorts provides clean estimates of the effect of military service and the G.I. Bill.

This paper exploits Bound and Turner's identification strategy to investigate the G.I. Bill's broader social impacts. While historians frequently credit the G.I. Bill with having created permanent changes in the structure of American society, most quantitative studies have been confined to analyses of its impact on education and earnings (Angrist and Krueger, 1994; Bound and Turner, 2002; Lemieux and Card, 2001; Stanley, 2003). There is reason to believe, however, that the G.I. Bill may have affected individuals' outcomes beyond their labor market opportunities. In particular, evidence suggests that education may reduce crime (Lochner and Moretti, 2004), reduce mortality (Lleras-Muney, 2005), and improve some outcomes among individuals' children (Currie and Moretti, 2003; Murnane, 1981; Oreopoulos, Page and Stevens, 2006; Thomas, Strauss and Henriques, 1991), so a natural question is whether the additional

⁶ The figure is based on the three 1% samples in the 1970 Census. Appendix Figure 1 shows participation rates created using the 1960 and 1980 Censuses.

education induced by wartime events had spillover effects onto other outcomes.⁷ Only a few studies have empirically explored the relationship between World War II, the G.I. Bill, and non-labor market outcomes,⁸ and to our knowledge, no one has yet investigated the impact that these historic events may have had on marital opportunities and marital sorting in the United States.

There are several mechanisms by which WWII and the G.I. Bill might have affected veterans' probabilities of marriage and their ability to attract higher "quality" spouses than they might have otherwise. First, positive assortative mating on education is well documented,⁹ and as noted above, it has been previously shown that cohorts with high conscription rates obtained more schooling than those who just missed the cutoff. Education is also associated with higher earnings, occupations and socioeconomic status. All of these outcomes might in turn affect the pool of available mates by changing both the social circles that individuals inhabit and their own attractiveness to potential partners. An individual's education may also change his or her spouse's behavior. For example, if education increases a man's earnings, then this might enable his wife to invest more in her own human capital.

⁷ Recent studies have documented that the Vietnam draft lottery had an impact on non-wage outcomes such as marital status, migration and health. See, for example, Angrist and Chen (2011), Conley and Heerwig (2011), McCarthy (2012), McCarthy (2013) and Malamud and Wozniak (2012). Similarly, Galiani, Rossi and Schargrodsky (2011) estimate the impact of military service on crime using the random assignment of men to military service in Argentina. ⁸ Bedard and Deschenes (2006) find that cohorts with higher rates of WWII participation were more likely to die prematurely (excluding deaths attributed to combat) and that higher death rates among these cohorts are associated with higher rates of military-induced smoking. Yamashita (2008) and Fetter (2011) find evidence of a fading relationship between G.I. eligibility and homeownership, and Page (2007) shows that the children of affected cohorts had lower probabilities of repeating a grade.

⁵See for example, Mare, 1991; Cancian, Danziger and Gottschalk, 1993; Jepsen and Jepsen, 2002; Juhn and Murphy, 1997, Pencavel, 1998; McCarthy, 2013. Our own calculations from the 1960, 1970 and 1980 Censuses, indicate that across all age groups, the correlation between husbands' and wives' schooling is between 0.52 and 0.62.

Second, military service might have an independent effect on marital outcomes. For example, the prestige of having served may have increased veterans' marital prospects. Veterans may have also learned skills during their service that could be transferred to the labor market, increased their earnings potential, and made them more attractive marriage partners. Previous studies by Angrist and Krueger (1994) and Lemieux and Card (2001) find no evidence that WWII veterans earned more than non-veterans, but the possibility that wartime service increased men's economic potential should nevertheless be kept in mind. On the other hand, physical and emotional disabilities resulting from combat may have reduced some veterans' marital prospects. We will explore these possible mechanisms in Section V.

II. Estimation Strategy

To begin with, consider the following reduced form equations

$$HEd_{ic} = \phi_1 HCohort_{ic} + \phi_2 (Post1927)_{ic} + \phi_3 X_{ic} + \mu_{ic}$$
(1)

$$Married_{ic} = \beta_1 HCohort_{ic} + \beta_2 (Post1927)_{ic} + \beta_3 X_{ic} + \mu_{ic}$$
(2)

$$WEd_{ic} = \varphi_1 HCohort_{ic} + \varphi_2 (Post1927)_{ic} + \varphi_3 X_{ic} + \mu_{ic}$$
(3)

where *HEd* measures the educational attainment of man *i* belonging to cohort c, *Married* is an indicator variable that is equal to 1 if individual *i* belonging to cohort *c* is married and is equal to zero otherwise, and *WEd* is the educational attainment of individual *i*'s wife. *HCohort* is a linear variable measuring the cohort (by birth year and birth quarter) to which the man belongs, and *X* is a vector of individual controls. We do not include measures of the individual's income or work experience since these may be affected by educational attainment. *Post1927* is a dummy variable that is equal to 0 for cohorts born before 1928 and 1 for cohorts born in or after 1928.

As Figure 1 and Table 1 make clear, the vast majority of men born after 1927 did not serve in WWII and would not have been eligible for G.I. benefits provided to WWII veterans. We can think of the pre 1927 cohorts as the "treatment" group, and the post 1927 cohorts as the "control" group. By including a linear trend, and focusing on cohorts born within narrow windows, it is reasonable to assume that the coefficient ϕ_2 identifies the change in men's educational attainment that resulted from the abrupt decline in conscription rates among men born after 1927. We can similarly estimate the effects of military service and the G.I. Bill on men's marital opportunities by estimating β_2 and φ_2 . It important to note, however, that because cohorts born close to 1927 (both before and after) effectively faced the same pool of potential partners, φ_2 captures the combined effect of any increase in wives' education levels that was experienced by the cohorts that were eligible for G.I. benefits, and the resulting crowd-out experienced by the cohorts who just missed the cutoff. In other words, given a fixed distribution of education among potential partners, gains in wives' education for one group of men were likely accompanied by declines for others. This means that the difference in wives' average educational attainment between the treatment group and the control group is, in all likelihood, larger than the gain that the treatment group experienced relative to what it would have experienced in the absence of the war (or the partial equilibrium effect). This should be kept in mind when interpreting the estimates throughout the rest of the paper.¹⁰

¹⁰ If the treatment and control groups were exactly the same size, and were pulling from exactly the same pool of women, then a reasonable approximation of the partial equilibrium effect would be one half of the estimated difference between the treatment and control groups. As more cohorts are added to the sample, however, the assumption that both groups are pulling wives from the same pool of women becomes increasingly tenuous and more assumptions need to be made in order to estimate the magnitude of the partial equilibrium effect.

This research design would be easy to implement, but the Korean War draft, which affected many men born after 1927, makes it hard to interpret. More than a third of the 1928 cohort in our sample served in Korea, and the fraction increases among later cohorts. Like those who served during WWII, Korean War veterans were also eligible for educational benefits, but unlike men subject to the WWII draft, men who wanted to avoid serving in Korea could obtain educational deferments. As a result, estimates based on simple comparisons between cohorts who turned 18 on either side of VJ day are likely to be compromised by the effects of the Korean War. Instead of estimating equations (1)-(3), we use Bound and Turner (2002) as a guide and estimate the following augmented equations

$$HEd_{ic} = \alpha + \phi_1 HCohon_{ic} + \phi_2 \%WWI_{ic} + \phi_3 \%Kore a_{ic} + \phi_4 \%Kore a_{ic} * HCohon_{ic} + \phi_5 X_{ic} + \eta_{ic}(1a)$$

$$Manied_{ic} = \alpha + \beta_1 HCohon_{ic} + \beta_2 \%WWI_{ic} + \beta_3 \%Kore a_{ic} + \beta_4 \%Kore a_{ic} * HCohon_{ic} + \beta_5 X_{ic} + v_{ic}(2a)$$

$$WEd_{ic} = \alpha + \phi_1 HCohon_{ic} + \phi_2 \%WWI_{ic} + \phi_3 \%Kore a_{ic} + \phi_4 \%Kore a_{ic} * HCohon_{ic} + \phi_5 X_{ic} + v_{ic}(2a)$$

where *%Korea* is the fraction of men in the individual's year and quarter-of-birth cell who identified themselves as Korean War veterans and the interaction term between *%Korea* and the linear trend allows for the possibility that the Korean conflict may have had a differential effect on later cohorts. This seems likely, as Korean War educational deferments were not introduced until 1951.¹¹

¹¹ For the sake of completeness, we have also estimated equations in which we replace %WWII and %Korea with a variable that measures the fraction of the cohort who served in either war. For the reasons described above, this specification does not seem ideal. Nevertheless, it produces estimates that follow the same pattern as our main estimates. Like our main estimates, they are positive, and often statistically different from zero, but they are generally smaller in magnitude than the estimates produced by equations 1a-3a.

These specifications also replace the *Post27* dummy with *%WWII*—the fraction of men in the individual's birth cohort who served during WWII and were thus eligible for G.I. benefits. This allows us to make use of the substantial variation in participation rates across quarter-ofbirth cohorts who turned 18 right around VJ day. The coefficients ϕ_2 , β_2 and φ_2 identify the average differences in outcomes between cohorts who were eligible for benefits and cohorts who were not eligible. Since our identifying variation is at the cohort level we collapse our individual level data into year and quarter of birth cells, and estimate equations (1a)-(3a) at the cell level.¹²

The success of our identification strategy hinges on the assumption that in the absence of the war, cross-cohort variation in individual characteristics would not have followed the same discontinuous pattern as WWII participation rates. One might be concerned that the Great Depression threatens this assumption since some of our control cohorts were born during the Great Depression, while all of the treated cohorts were born when the economy was booming. Dehjia and Lleras-Muney (2004) document that infants conceived during recessions are healthier than infants conceived when the economy is doing well; others have found that health at birth is a positive predictor of labor market success (e.g. Behrman and Rosenzweig, 2004; Black et al., 2007; Oreopoulos et al., 2008; Royer, 2009). If these effects play out in our estimates, however, they will cause us to underestimate the impact of WWII on assortative mating. Thomasson and

¹² Seminar participants have proposed two alternative identification strategies that we feel are less compelling than cohort level variation in benefit eligibility: one suggestion has been to follow the approach used by Stanley, who identifies the impact of G.I. benefits using variation in take-up rates across eligible cohorts. The drawback to this approach is that we do not have a solid understanding of *why* take-up rates varied. Whatever underlies the variation might also have affected marital sorting. The second suggestion is to use cross-state variation in mobilization rates, similar to Acemoglu, Autor and Lyle (2004). However, that study also documents correlations between state mobilization rates and other state characteristics, and those characteristics may be correlated with marital outcomes. In previous work, Page (2007) has found that estimates of the impact of G.I. benefits that used state level mobilization rates as an instrument for eligibility were sensitive to the inclusion of state level control variables.

Fishback (2013) find that the economic outcomes of most adults who were born during the Great Depression were not compromised.¹³ Further, the high unemployment rates that characterized the Great Depression occurred during the early 1930s, several years after the "discontinuity" upon which our identification rests.

We further minimize the probability that the Great Depression, or other time-varying factors, contaminate our estimates by including a linear time trend and focusing on men born within a narrow time interval.¹⁴ Our estimates are robust to confining the analyses to cohorts conceived before 1930. We have also used data from the Panel Study of Income Dynamics (PSID) and the 1973 Occupational Change in a Generation Survey (OCG) to investigate the extent to which pre-service family background characteristics varied across these cohorts. In no case could we reject the null hypothesis that these characteristics were the same across cohorts, although this is partly due to the fact that the samples are small and yield imprecise estimates.¹⁵

A related concern is that any sample that is used to study the impacts of the G.I. Bill will only include those men who survived the war. A potential issue is that cross-cohort variation in the probability of experiencing combat and risk of death may induce cross-cohort variation in

¹³ Except among individuals born in very poor southern states. Our results are robust to exclusion of these states.

¹⁴ Replacing the linear trend with year-of-birth dummies and quarter-of-birth dummies yields very similar results.

¹⁵ Family background variables include: father's education (PSID), and whether the individual lived with both parents at age 16, his father's occupation at age 16, and his parents' educational attainment (OCG). The OCG data also include retrospective reports on parents' income when the individual was age 16. The parental income data are reported in bins. It is unclear whether respondents are reporting nominal or real dollars. This makes it difficult to interpret statistical analyses using this variable, since different cohorts turned 16 in different years. In a few specifications, we find that the fraction of individuals coming from high income families is larger among the younger cohorts in our sample, which would be consistent with estimates of G.I. Bill effects that are biased downward. Since the OCG data do not include quarter of birth, these analyses are based on, at most, 15 data points.

unobserved characteristics. Suppose, for example, that more "able" veterans were less likely to be on the front lines. Then, since later cohorts of veterans were also less likely to engage in combat, the oldest cohorts in our sample would be positively selected. Our OCG and PSID analyses provide no evidence that family background characteristics vary across cohorts, but we investigate the possibility of cross-cohort variation in unobserved characteristics further by estimating the rate of return to education for each cohort. If older cohorts are more "able" than younger cohorts, then their rate of return should be higher. The results of this exercise can be seen in Appendix Figure 2. While there is a clear downward trend in the estimated rate of return among cohorts born during the first half of the century, estimates for the cohorts born immediately before and after 1927 do not differ significantly from this trend. A related issue is that cross-cohort differences in the probability of combat are likely to have led to differences in male/female sex ratios, which may have had an independent effect on marital sorting. We explore this possibility in Section V.

Our estimation strategy also assumes that the direct effects of the G.I. Bill were concentrated almost exclusively on men, and that female education levels did not respond in the same discontinuous way. Given that only about 3% of women born during this period served in World War II,¹⁶ this seems like a reasonable assumption, but we will explore it more directly in Section V. It may also be useful to keep in mind that among the cohorts included in our analyses, only about 9% were married at the time they began their service.¹⁷

III. Data

¹⁶ Authors' calculations based on the 1980 Census.

¹⁷Authors' calculations based on Army enlistment records available through The National Archives Access to Archival Database (AAD), online at http://aad.archives.gov/aad/. Estimates are not expected to differ for other branches of the Armed Forces.

Our analyses are based on the three 1% samples of the 1970 Integrated Public Use Microdata Series (IPUMS), which includes both individual and household level data from the 1970 decennial census. Each of these files provides a 1/100 sample of individuals in the United States. By aggregating, we are able to create a 3% sample of all men living in the United States in 1970. We chose the 1970 Census over the 1960 Census because of its larger sample size and to allow sufficient time for the youngest cohorts to make their education and marital decisions.¹⁸ We chose the 1970 Census over the 1980 Census because the 1980 Census shows notably higher levels of schooling among our cohorts, which likely results from factors unrelated to the G.I. Bill such as differential mortality, over-reporting of educational attainment that increases with age, and later enrollment in college (Bound and Turner, 2002). Results using the 1980 Census are qualitatively similar but are often (as expected) smaller in magnitude.

We begin by focusing on men who were born between 1923 and 1929, and then add successive post 1929 cohorts, until we reach the cohort that was born in 1938. These cohorts are close in age and should thus have had similar life experiences prior to the war. In addition, the 1923-1927 cohorts faced similar probabilities of being drafted. We limit the sample to white men who were born in the United States, since previous studies have shown that the effects of WWII and the G.I. Bill were quite different across racial groups.¹⁹ We also exclude all men for whom information on race, sex, age, or veteran status (men only) was allocated.

¹⁸ The 1960 PUMS is a 1% sample.

¹⁹ Turner and Bound (2003) show that it had little effect on the collegiate outcomes of black veterans living in Southern states, probably because their educational choices were already so limited. As a result, the G.I. Bill may have exacerbated the education gap between Southern blacks and whites.

The 1970 Census reports individuals' completed years of schooling. We use this information to create a continuous measure of husbands' years of college education (1-4 years) based on whether they completed 13, 14, 15 or 16+ years of school. We define a WWII veteran as anyone who served in World War II. In our main analyses, a Korean War veteran is defined as anyone who indicated that they served in the military but not during WWII. In our initial replication exercises, however, we follow Bound and Turner, and define a Korean War veteran as anyone who served in the Korean War.

Table 1 shows descriptive statistics for all men, regardless of marital status, in our sample. Our analyses are based on between 136,666 and 393,629 individuals, but since our identifying variation is at the birth cohort level, the analyses aggregate our individual observations into cells defined by year and quarter of birth. Consistent with previous studies, we find that rates of military service are around 80% among the oldest cohorts, and that participation quickly falls to nearly zero for cohorts born after 1928. In contrast, Korean War service is common among men born between 1929 and 1935. Across all cohorts, completed schooling shows an upward trend, but there is no evidence of a trend in marriage probabilities.

IV. Results

IV.A. Effects of WWII and the G.I. Bill on Men's Educational Attainment

We begin by exactly replicating Bound and Turner's estimates of the relationship between WWII participation and educational attainment, and then extend their empirical framework to look at other outcomes. Table 2 provides between-birth-cohort estimates of the effect of World War II and Korean War service on men's collegiate attainment. The estimates presented in the first six columns are differentiated by the number of post-treatment cohorts that are included in the sample. As discussed by Bound and Turner, the benefit of analyzing fewer cohorts is that the resulting estimates are unlikely to be biased by the presence of other cross-cohort differences, but the cost is that the identifying variation misses the youngest cohorts who are least likely to be eligible for G.I. benefits. Across the different samples, a 100% increase in the probability of serving is associated with an increase of between 0.3 and 0.4 years of education.²⁰ The standard deviation in men's education is approximately 3 years, so this represents a substantive difference in educational attainment.

Bound and Turner discuss the potentially contaminating effects of the Korean War, and note that as younger cohorts are added to the analysis these effects are less and less likely to be well captured by the *%Korea* variable. In order to address this concern, they add interactions between the percent of the cohort that participated in the Korean War and a linear trend. When cohorts born during the second half of the 1930s are included, they also add a quadratic trend and an interaction between the quadratic trend and the fraction of the cohort who served in Korea. This allows the effects of service in Korea to vary across birth cohorts in a non-linear way, which is a plausible assumption given that Korean War educational deferments were not introduced until 1951.

We replicate this part of their analysis in Columns 7-9 and show that when we include these controls the estimated coefficients on *%WWII* fall slightly. The estimate in column 7 is most affected because compared to columns 8 and 9, the analysis includes fewer post-treatment cohorts, which makes it harder to simultaneously identify the effects of the war from the linear

²⁰ All of our estimates exactly match Bound and Turner's except for those based on the 1923-32 cohorts. Our estimate using those cohorts is 0.42, whereas Bound and Turner's estimate is 0.30. Since the two sets of estimates are based on exactly the same specification, and all of the estimates generated by the other samples match, we believe that the difference between the estimates for the 1923-32 cohorts is likely due to a typographical error.

trend. The standard error estimate also increases. The estimate in column 8 is guite similar to that in column 6, but here the linear trend and its interaction with %Korea may not sufficiently control for the part of the cross-cohort variation in educational attainment that is generated by Korea. Because column 9 includes a more complete set of Korean War controls, we believe (like Bound and Turner) that these estimates, along with the estimates presented in the first few columns of Table 2, represent the cleanest estimates of the combined impact of WWII service and the G.I. Bill on men's schooling. The estimates in the bottom panel of Table 2 are based on the same identification strategies but control for Korean War service a little differently. Figure 1 suggests that among the youngest cohorts in our sample, there are many men who served in the military but do not identify themselves as veterans of either WWII, or the Korean or Vietnam wars. Men born in 1935, for example, are nearly equally likely to identify themselves as Korean War veterans or as having engaged in "other" military service (not WWII or Vietnam). It is likely that many of these men did not classify themselves as Korean War veterans because their primary period of service was after January of 1955. Nevertheless, many of these men would have still qualified for educational benefits under the Korean War G.I. Bill since anyone who entered the military prior to Feb 1, 1955 and served for ninety days was eligible. When we more broadly control for the effects of the Korean War by including men who identify themselves as serving either in Korea or at "any other time"²¹ we find that the estimated effects of both WWII and Korean War service increase substantially (columns 6,7 and 9).²² We carry forward this definition of "probable" Korean War service throughout the rest of the paper, but our findings are not affected by this decision in any substantial way.²³

²¹ i.e. Not during the specific war periods listed in the Census survey.

 $^{^{22}}$ As would be expected from Figure 1, the estimates in columns 1-4 barely change.

²³ Results available from the authors upon request.

IV.B. The Relationship Between WWII, the G.I. Bill and Assortative Mating

Given the clear association between WWII, the G.I. Bill and men's education, it is natural to consider whether these historical events had spillover effects into other dimensions of family life. We begin to explore this possibility in Table 3, where we show estimated effects on marital status and wives' educational attainment using our preferred specifications.²⁴ We find no evidence that the G.I. Bill had any effect on the probability of being married, separated, or divorced. These estimates are unsurprising since cultural norms in the 1940s encouraged marriage, and there was no scarcity of "available" women. Among the cohorts used in our sample, the male/female ratio was around 0.98. In other words, the number of women exceeded the number of men. Given this, we would not expect to find that WWII cohorts crowded younger male cohorts out of marriage, rather, we would expect WWII service and the GI Bill to change the type of women that each group married. In fact, we find that WWII improved men's ability to attract higher "quality" spouses: cohorts with high WWII participation rates married women with more years of schooling, higher probabilities of having graduated from high school, and higher probabilities of having enrolled in college. The lack of a relationship between wives' bachelor's degree status and husbands' WWII participation may be due to the fact that only small numbers of women graduated from college during this period.²⁵

These reduced form estimates suggest that WWII and the G.I. Bill had substantive spillover effects beyond their effect on men's educational attainment. The estimated coefficients in column 4, for example, indicate that relative to men who just missed the cutoff, those who qualified for the G.I. Bill married women who had approximately 0.4 additional years of

²⁴ Results based on other specifications are available on request.

²⁵ Our calculations from the census indicate that fewer than 9% of white women born between 1923 and 1930 had bachelor's degrees.

education. Since these two groups of men effectively faced the same marriage pool, this estimate potentially encompasses gains to the treatment group that came at the control group's expense. The estimate is therefore an upper bound estimate of what the G.I. bill's partial equilibrium effect would have been if the control group's marital opportunities had remained constant.

V. Mediating Relationships and Further Interpretation

To clarify the nature of our estimated treatment effects, we next explore possible mechanisms. We first examine the role of direct channels other than the educational benefits provided by the G.I. Bill, which include the possible impacts of military service itself, G.I. housing benefits, and differing sex ratios across "treatment" and "control" cohorts. We also conduct more general falsification tests that are motivated by the fact that, among women, G.I. benefit eligibility and take up was low. Finally, we consider whether our estimates reflect changes in sorting vs. changes in human capital investments that took place *after* marriage by looking at cohort level patterns in the age gap between husbands and wives.

V.A. Distinguishing between the Effects of Military Service and Education Benefits

As described earlier, the estimates in Tables 2 and 3 represent the combined effect of military service and G.I. benefits. The experience of serving in WWII may have had either positive or negative impacts on marital outcomes. One piece of evidence in this regard is that WWII veterans appear to have earned no more than non-veterans (Angrist and Krueger, 1994; Lemieux and Card, 2001), but earnings are only one measure of success, and in principal one can imagine the bias going in either direction. The general public viewed returning veterans as

18

heroes,²⁶ which may have positively influenced their social interactions and made them more attractive marriage partners. At the same time, the stress resulting from combat may have left permanent scars on other veterans' abilities to make social connections and provide for their families.

In order to glean some insight into how the impact of military service contributes to our estimates, we look at variation in education and spousal quality among cohorts of men who came of age around the time of the First World War. Although these men received a generous monetary bonus for their service, educational benefits were not available to World War I veterans. Comparing the education and marital outcomes of cohorts near the World War I "break" may, therefore, provide some information about the likely influence of military service relative to educational benefits. In particular, differences between cohorts who served during WWI and those who narrowly missed the cutoff can be roughly thought of as an upper bound estimate of the impact of service.

We explore this phenomenon using data from the 1930 and 1940 Censuses. Information on WWI service comes from the 1930 Census, and information on educational attainment is taken from the 1940 Census. These Census files do not record year and quarter of birth; rather, age is reported in years. Thus, we assume that each survey respondent's birthday falls after the census was taken in April, and use this to estimate his year of birth. Following Fetter (2013), we look at men born between 1891 and 1902, and look for a change in outcomes across a participation cutoff for cohorts born between 1896 and 1897. Table 4 shows the estimated coefficient on a variable that controls for the fraction of each cohort that participated in WWI,

²⁶ E.g. Mettler (2005), p. 10 "Importantly, their deservingness for the generous benefits was considered to be beyond question, given that through their military service they had put themselves in harm's way for the sake of the nation."

for a series of regressions with different dependent variables (men's educational attainment, marital status and wives' educational attainment). Each regression equation also includes a linear trend. The coefficient estimates are small and noisy, thus providing no evidence that World War I participation affected any of these outcomes.²⁷ This strengthens the likelihood that the estimates in Tables 3 are driven by cross-cohort variation in education benefits.

V.B. The GI Bill and Homeownership

In addition to educational benefits, the G.I. Bill also guaranteed generous home and business loans that made it possible for approved lenders to provide no-down payment mortgages to returning veterans. Between 1944 and 1952, the Veterans Administration guaranteed nearly 2.4 million home loans. Recent work by Yamashita (2008) and Fetter (2013) suggests that these benefits had a significant impact on white veterans' rates of homeownership during the post-war period, although the advantage disappeared by 1980. This suggests that our assortative mating results might be driven by veterans' early access to housing rather than their higher education levels. In order to investigate this possibility we create a measure of cohort-level homeownership rates from the Census and include this variable as an additional control variable.²⁸

The results of this exercise are shown in Table 5. Consistent with previous studies' evidence of fade-out effects, we find no evidence that G.I. benefit eligible cohorts were more

²⁷ We obtain the same qualitative result when we replace the %WWI variable with a dummy variable indicating that the cohort was born after 1896.

²⁸ Specifically, we create a dummy variable that is equal to 1 if the individual reports that his living quarters are owned or bought by himself or someone in his household, and 0 if the individual reports that his living quarters are rented or occupied without payment of cash rent. We then use this variable to calculate the fraction of each cohort who owned their own home. We have also used the 1960 Census to create a comparable variable.

likely to own a home in 1970 than their ineligible counterparts. However, in some specifications, owning a home is positively correlated with the probability of being married, and it is always positively associated with wife's years of education.²⁹ This suggests that the improvements in veterans' access to housing may have affected their ability to attract higher quality wives. However, inclusion of the housing variable has virtually no impact on our estimates of the impact of WWII service on wives' schooling.³⁰ We have also estimated our regressions including homeownership rates calculated from the 1960 Census since this is the Census year for which both Yamishita and Fetter find evidence of homeownership differences across cohorts.³¹ Including the 1960 control variable has no substantive impact on the estimated *%WWII* coefficients either. Taken together, these results suggest that the estimates presented in Table 3 are not driven by the homeownership benefits that were associated with the GI Bill.

V.C. Cross-cohort Differences in Sex Ratios

High rates of military service among our treatment cohorts also lead to lower

male/female ratios. About 16 million men served in World War II, and of these, approximately

405,000 died.³² Becker (1981) suggests that sex ratios could have strong implications for

assortative mating: in particular, a decrease in the number of men implies that men should be

²⁹ We obtain similar results when we use the other measures of wives' educational attainment that are included in Tables 3-5. For the sake of brevity, we do not include all of those measures in Table 7.

³⁰ Results are virtually identical if we restrict our definition of home ownership to include only heads of households.

³¹ Unlike Yamishita and Fetter, we do not find evidence that G.I. benefit eligible cohorts were more likely to own a home in 1960 than their ineligible counterparts. The discrepancy appears to emanate from differences in the way the Korean War is incorporated into the different analyses. Yamishita does not control for the effects of the Korean War at all. Fetter's analysis assumes that the impact of participating in WWII and participating in Korea would be the same for a given cohort. Our specification provides more flexibility on this front.

³² In contrast, Korean War participation rates were much lower (especially for our cohorts) and resulted in only 36,500 deaths

able to mate with higher quality women than would otherwise be possible. A few previous studies have investigated how changes in the sex ratio resulting from WWII affected marriage in Europe (Brainerd, 2006; Kvasnicka and Bethmann, 2013) but to our knowledge no one has yet investigated the impact that these historic events may have had on marital opportunities and sorting in the United States.³³

Figure 2 plots the sex ratio by year and quarter of birth, and shows a substantive difference in the ratio between the pre and post 1927 cohorts. The figure is based on the 1960 Census because differences in the sex ratio are much smaller by 1970.³⁴ It is also closer to the time period during which we expect most of these cohorts made their marital decisions. Since men often marry women whose age is within a few years of their own age, our measure of the sex ratio divides the number of men in each quarter and year of birth by the average number of women in quarter and year of birth cohorts falling within two years of the male cohort. We have tried several alternative measures and obtain very similar, or smaller, results.³⁵

Figure 2 shows that relative to cohorts born after 1927, cohorts born in the pre-1927 period experienced a male/female ratio that was 2.5 percent lower. In order to test whether this phenomenon is driving our estimates we include the sex ratio as an additional control variable in our main regression. The results of this exercise are presented in Table 6, where we see that including this variable has essentially no impact on the estimated relationship between WWII service and the probability of marriage or wife's education.

³³ Bitler and Schmidt (2011) and Lafortune (2008) estimate the impact of sex ratios on assortative mating in the U.S. with respect to contexts other than World War II. ³⁴ E³⁴ E³⁴

³⁴ Figure available by request.

³⁵ For example, we have calculated the sex ratio using only men and women who belong to the same birth cohort.

V.D. Effects of WWII and the GI Bill on Women's Education

Another possibility is that our results reflect changes in women's own schooling levels that were induced by the war. It is unlikely that female military service or female responses to own G.I. benefits are driving our results because only about 3% of women born between 1923 and 1938 served during WWII,³⁶ but the absence of potential partners during the war years may have made investments in education more attractive. Such investments will only threaten the interpretation of our estimates if women's educational attainment follows a discontinuous pattern similar to men's. Furthermore, using the 1960 Census, Jaworski (2014) finds that women coming of age during WWII had lower (not higher) levels of education, and that by 1970 the impacts of WWII were no longer distinguishable from zero.

Nevertheless, we look for discontinuities in female schooling levels by matching our measure of male WWII participation by year and quarter of birth to cohorts of women born in the same quarter and year, and then estimating versions of equations 1a-3a in which the dependent variables are replaced with measures of women's educational attainment. The top panel of Table 7 displays the results of this exercise. There is little evidence that male participation rates predict education levels among women in the same cohort. Very few of the estimates are statistically different from zero, and the estimates that are significant are not consistently positive. The lower panel of Table 7 presents the results from the same exercise, only matching women to men who are two years older, to better approximate the "typical" age gap between husbands and wives. As in the top panel, most of the estimates are indistinguishable

³⁶ We have estimated the impact of female military service on women's schooling by estimating regressions similar to equations 1a-3a, and, as expected, find little evidence of variation in women's educational attainment across cohorts with differential access to G.I. benefits. The results of this exercise are available from the authors upon request.

from zero. We conclude that cohorts of women for whom there were many absent men did not respond by increasing their own education levels.

V.E. Marital Sorting vs. Post-Marriage Investments

Our analyses suggest that the cohort effects we estimate are not likely to be driven by "competing events." We find no evidence that the impact of military service, changes in marital opportunities that resulted from cohort differences in sex ratios, or housing benefits provided through the G.I. Bill are associated with the patterns in our data. One interpretation of our results, therefore, is that the change in men's schooling levels that resulted from their access to educational benefits allowed them to gain access to a "higher quality" pool of potential mates. An alternative interpretation that is consistent with the evidence is that WWII veterans married the same women that they would have married in the absence of the war, but that because of the husbands' higher education levels, their wives were subsequently able to increase their own schooling.

Given that only 9% of men were married at the time they entered the service, we think that the latter mechanism is unlikely to be driving our estimates. We cannot definitively rule this possibility out, but Figures 3A and 3B provide some evidence of changes in marital sorting by age that mimic the differences that we see in wives' educational attainment. If the G.I. Bill did not induce a change in marital sorting, then we would expect the average age gap between husbands and wives to remain more or less constant. Figure 3A plots the standard deviation of the age gap between husbands and their wives. The standard deviation captures the degree of heterogeneity in age sorting within cohorts, and we see that, consistent with a change in age sorting, the standard deviation increases substantially for cohorts born between 1924 and 1930. This tells us that affected cohorts were matching with women from a wider range of birth years than was the norm for men who came of age both earlier and later.

Similarly, Figure 3B plots the average husband-wife age gap for male cohorts born between 1910 and 1940. This figure shows a distinct increase in the magnitude of the gap right around the 1927 cutoff, and documents that men who just missed eligibility for WWII benefits married women who were discontinuously younger than the women who paired up with their eligible counterparts. Appendix Table 1 provides more detail, including the full distribution of wives' birth years for each male cohort in our sample. Note that while Figures 3A and 3B both provide evidence of changes in marital sorting by age, the pattern in Figure 3B is the opposite of what one would expect if pre-1927 cohorts simply "poached" women from male cohorts who just missed the cutoff. The changes in sorting induced by the war were clearly more complex. Nevertheless, the figures make clear that cohorts who were able to take advantage of G.I. benefits married different women than they would have in the absence of these historical events. Figure 3B also suggests that because the treatment group married relatively older women than they would have otherwise, the extent to which the treatment group's behavior reduced spousal quality among the control group may have been quite limited. The estimated coefficients in Table 3, therefore, may come quite close to capturing a partial equilibrium effect. Both figures clearly imply that our main results are more likely to be driven by changes in marital sorting than by changes in wives' educational investments that took place after marriage.

VII. Conclusion

A number of previous studies have documented that World War II and the G.I. Bill had substantial effects on men's educational attainment, but the degree to which these historical

25

events affected other social outcomes is not well understood. In this paper we exploit quasirandom variation created by the abrupt decline in WWII manpower requirements to investigate whether the impact of WWII and the G.I. Bill spilled over onto marital sorting. We find substantive evidence that they did: cohorts of men who were eligible for G.I. benefits married women who had approximately 0.4 more years of education than cohorts who just missed the eligibility cutoff. Their wives were also discontinuously older.

While our estimation strategy does not allow us to separately identify the relative impacts of military service from the G.I. Bill, the most likely mechanism is that men's marital opportunities were changed by the additional education that they received. Similar analyses of cohorts who came of age during WWI do not produce analogous results-there is no evidence of discontinuities in education levels for WWI cohorts or their wives-and if our estimates for WWII and the G.I. Bill operated through the effects of military service then previous generations of servicemen would likely exhibit similar patterns. Additional analyses also indicate that our estimates are not likely driven by combat related changes in the sex ratio, or by housing benefits that were provided through the G.I. Bill. We find no evidence that they are driven by an independent effect of the G.I. Bill on female schooling levels. Finally, the fact that affected cohorts of men married women who were both more educated and relatively older than men who just missed qualifying for G.I. benefits eliminates the possibility that our estimates are driven by changes in wives' schooling that took place after they were married. In short, other potential mechanisms do not appear to explain the observed patterns, leaving the changes in men's educational attainment induced by the G.I. bill as the most likely explanation.

Our estimates are of substantial magnitude, but one should be careful about using them to make specific policy recommendations. One reason for this is that our analyses neither isolate

the partial equilibrium effect of giving a random man access to college, nor do they identify the general equilibrium effect of increasing everyone's access. In addition, women's education levels and labor market opportunities have changed markedly in the past 70 years, which hinders our ability to extrapolate our findings to the present day. Nevertheless, our results underscore the idea that investments in human capital may yield substantive marriage market returns, and they strongly imply that at least some of the assortative mating we observe in society can be manipulated by policy.

Table 1: Summary Statistics

World War II, regardless of their military service status in other periods. The variables % Korea and %Korea and Interwar are the fraction of men who identified themselves as having participated in those conflicts but did not also serve in World War II. Wives' Highest Grade Note: The sample is composed of white men. The variable %WWII is the fraction of all men in a given birth cohort who were veterans of *Completed* is based on the wives of the married men in our sample.

Trend²

Source: 1970 Integrated Public Use Microdata Series (IPUMS, three 1% samples)

Note: The sample is composed of white men. The variable *World War II Service* is the fraction of all men in a given birth cohort who were veterans of World War II, regardless of their military service status in other periods. The variables *Korean War Service* and *Korean & Interwar Period Service* are the fraction of men who identified themselves as having participated in those conflicts but did not also serve in World War II. The time trend is defined as year of birth - 1929 + (quarter of birth/4). We calculate Huber-White standard error estimates.

Table 4: Reduced Form Estimates of the Effect of WWI Service on Men's College Education Marital Status and Wife's Educational Attainment

Source: 1930 and 1940 Integrated Public Use Microdata Series (IPUMS, 1% samples)

Note: Estimates are based on birth-year cell level averages for white men born between 1892 and 1901. Birth-year averages for education come from the 1940 Census. Birth-year averages for World War I service come from the 1930 Census. *World War I Service* is defined as the fraction of all men in a given birth cohort who were veterans of World War I. Each regression contains a time trend defined as year of birth. We calculate Huber-White standard error estimates.

Table 6: Reduced Form Estimates of the Effect of WWII Service on MaritalStatus and Wife's Educational Attainment Controlling for the Male/FemaleSex Ratio

Source: 1970 Integrated Public Use Microdata Series (IPUMS, three 1% samples)

Note: The sample is composed of white men. The variable *World War II Service* is the fraction of all men in a given birth cohort who were veterans of World War II, regardless of their military service status in other periods. The variables *Korean War Service* and *Korean & Interwar Period Service* are the fraction of men who identified themselves as having participated in those conflicts but did not also serve in World War II. We define the Sex Ratio as the number of men in a birth cohort divided by the average number of women born in the previous and following eight quarters. The time trend is defined as year of birth - 1929 + (quarter of birth/4). We calculate Huber-White standard error estimates.
